The Short, the Long, and the Consequences of VAR Analysis For Structural DSGE Estimation

Master's Degree in Applied Economics; Economic Data Analytics

University of Padova; Supervisor Prof. Efrem Castelnuovo

Lorenzo Del Col

July 28, 2026

Abstract

Truncation bias could be a severe problem regarding structural VAR analysis (De Greave and Westermark) (DGW2025) claims that the role of lag choice in SVAR is crucial to correctly identify IRFs, and they claim that choosing long lags solve the bias and, surprisingly, this reduce the variance of the point estimate. CEE2005 is a classic paper that studies the effects of monetary policy shock in the economy. Particularly their DSGE is calibrated ex-ante using matching the model's IRFs with the ones estimated from the VAR analysis. The aim of this thesis is to perform the (DGW2025) exercise, see if and how the IRFs changes, analys how the DSGE model calibration vary and if the model is consistent to this new empirical way to estimate the VARs. If so, we want to understand more about the claimed variance reduction caused by the solution of the truncation bias how works in the Frequentist and Bayesian world.

1 Introduction

Provide the background of your topic, state the research problem, and outline the structure of your thesis here. Maybe I have switched the latex writing in VS Code

1.1 Research Question

Clearly define what your thesis aims to solve or investigate.

2 Theoretical Framework

Discuss the existing literature and the theoretical models that underpin your research.

3 Methodology

Explain the empirical strategy, models, and data you are using.

4 Empirical Results

4.1 From the state-space solution to a VAR(∞)

The state-space solution. Following Ravenna (2007), the recursive equilibrium law of motion of a linearised DSGE model is

$$y_t = Px_{t-1} + Qz_t, \tag{1}$$

$$x_t = Rx_{t-1} + Sz_t, \tag{2}$$

$$Z(L)\, z_t = \varepsilon_t, \tag{3}$$

where x_t is the $n \times 1$ vector of endogenous states, z_t the $m \times 1$ vector of exogenous states (structural shocks), y_t the $r \times 1$ vector of controls, and ε_t is $m \times 1$ white noise with $\mathbb{E}(\varepsilon_t \varepsilon_t') = \Sigma$ diagonal. The polynomial $Z(L) = [I - Z_1 L - \cdots - Z_q L^q]$ governs the persistence of the shocks.

Step 1: eliminate the endogenous states. Define $G(L) \equiv [I - RL]$ and write (2) as $G(L)x_t = Sz_t$. Assuming $G(L)$ invertible,

$$x_{t-1} = G(L)^{-1} SL z_t. \tag{4}$$

Step 2: the moving-average form. Substituting (4) into (1), and taking the observable vector to be $\widehat{Y}_t = y_t$ (the econometrician observes the controls but *not* the states),

$$y_t = Qz_t + PG(L)^{-1} SL z_t. \tag{5}$$

This is a VMA(∞). The moving-average term is the direct consequence of x_t being unobserved.

Step 3: the VARMA (i.i.d. shocks). Let $Z(L) = I$, so $z_t = \varepsilon_t$. Assume Q is invertible, which requires $r = m$, and define the reduced-form innovations

$$\eta_t \equiv Q\varepsilon_t = Qz_t, \tag{6}$$

so that Q is the theoretical matrix mapping structural shocks into reduced-form innovations. Then (5) becomes $y_t = \eta_t + PG(L)^{-1}SQ^{-1}L\,\eta_t$. Using the determinant–adjoint identity $G(L)^{-1} = D_G(L)\,|G(L)|^{-1}$, where $|G(L)|$ is a scalar polynomial of order n and the adjoint $D_G(L)$ is of order $n-1$, and multiplying through by $|G(L)|$:

$$\underbrace{|G(L)|\,y_t}_{\text{AR part}} = \underbrace{\Big[\,|G(L)|\,I + PD_G(L)SQ^{-1}L\,\Big]}_{\equiv\, G^*(L)}\eta_t \;=\; G^*(L)\,\eta_t. \tag{7}$$

Equation (7) is a VARMA(n,n) in *final equations form*: the autoregressive operator is scalar times the identity, so each component of y_t depends only on its own lags. Since $|G(0)| = 1$ and $G^*(0) = I$, the representation is unique.

Step 4: inverting the MA part. If $G^*(L)$ is invertible, premultiplying (7) by $G^*(L)^{-1}$ isolates the innovations:

$$|G(L)|\,G^*(L)^{-1}y_t = \eta_t. \tag{8}$$

Writing $G^*(L)^{-1} = D_{G^*}(L)\,|G^*(L)|^{-1}$, the adjoint $D_{G^*}(L)$ is of finite order, but the reciprocal of the scalar operator $|G^*(L)|$ expands as

$$\frac{1}{1-aL} = \sum_{j=0}^{\infty} a^j L^j, \tag{9}$$

which is of infinite order unless $|G^*(L)|$ is constant. Hence:

$$\boxed{\text{the DSGE solution generically implies a VAR}(\infty);} \tag{10}$$

a finite-order VAR(p) exists *if and only if* $|G^*(L)|$ is of degree zero in L, i.e. $G^*(L)$ is unimodular (**?**, p. 245).

Step 5: persistent shocks. With $Z(L) \neq I$, define $\widetilde{Z}(L) \equiv QZ(L)Q^{-1}$, so that $QZ(L)^{-1}\varepsilon_t = \widetilde{Z}(L)^{-1}\eta_t$. Then

$$|\widetilde{Z}(L)|\,|G(L)|\,y_t = G^*(L)\,D_{\widetilde{Z}}(L)\,\eta_t, \tag{11}$$

which, since $|\widetilde{Z}(L)|$ is of order qm, is a

$$\text{VARMA}\big(n+qm,\; n+q(m-1)\big) \tag{12}$$

process. Shock persistence therefore *raises* the autoregressive order required to represent the data.

Step 6: the VAR(∞) in explicit form. An equivalent and more transparent route (Corollary 2.2 in Ravenna, 2007) solves (1) for $z_{t-1} = Q^{-1}(y_{t-1} - Px_{t-1})$ and substitutes into (2), giving $H(L)x_t = SQ^{-1}y_{t-1}$ with

$$H(L) \equiv \big[I - (R - SQ^{-1}P)L\big]. \tag{13}$$

If $H(L)$ is invertible, the observables satisfy

$$y_t = P\sum_{j=0}^{\infty}\big[R - SQ^{-1}P\big]^{j} SQ^{-1}\, y_{t-j-1} \;+\; \eta_t. \tag{14}$$

Equation (14) *is* the VAR(∞), written out: the coefficient matrix attached to y_{t-j-1} is $P\,[R - SQ^{-1}P]^{j}\,SQ^{-1}$.

Interpretation. The matrix $R - SQ^{-1}P$ is the counterpart of $A - BD^{-1}C$ in Fernández-Villaverde et al. (2005); Ravenna notes that (14) "is the derivation obtained in Fernandez-Villaverde et al. (2005)". Two distinct questions follow. *Existence*: the VAR(∞) is well defined if all eigenvalues of $R - SQ^{-1}P$ lie inside the unit circle — the "poor man's invertibility condition". *Accuracy*: the eigenvalue *moduli* govern the geometric rate at which the coefficients in (14) decay, and hence the size of the bias incurred by truncating the lag structure at finite p. An eigenvalue close to unity implies coefficients that remain non-negligible at long lags, so that a short-lag VAR is a poor approximation to the model-consistent representation of the data.

5 Conclusion

Summarize the main takeaways, discuss the policy implications, and mention any limitations of your work.

Firm-specific capital ($\xi_{p,fs}$)	0.3372	0.1055	0.6448	0.3655	0.8884
	(-)	(-)	(-)	(-)	(-)

Investment adjustment cost in VAR with 6 lags has a point estimate of 2413 with a standard deviation of 7400. This is a good result in the sense that matches perfectly the ACEL2005 working paper, they estimate the baseline model with a VAR with 6 lags as robustness. The second thing that we can learn from this is that probably the likelihood function of this parameter int he underlying DSGE model, when matched with a VAR 6 is complitely flat. The maximum likelihood estimator is not able to find a maximum point

B.2 Implied Duration from Calvo Price Table: all lags

Table 2: Implied Average Time between Re-Optimization

Model Spec.	**VAR** $p = 4$	**VAR** $p = 6$	**VAR** $p = 8$	**VAR** $p = 10$	**VAR** $p = 12$
Homogeneous Capital Model					
Calvo ($\xi_{p,hom}$)	0.82	0.68	0.82	0.59	0.90
Duration (quarters)	**5.6**	**3.1**	**5.6**	**2.5**	**9.6**

	(0.0537)	(0.0572)	(0.0454)	(0.0453)	(0.0203)
Inv. adj. cost (S'')	3.1915	2490.6922	5.6111	8.7262	6.8431***
	(2.5697)	(7331.0985)	(4.6727)	(5.4036)	(2.3306)
Money demand elast. (ε)	0.8580***	0.8242***	0.9859***	0.7704**	0.8346***
	(0.1943)	(0.1897)	(0.2388)	(0.3083)	(0.1944)
			Implied Price Stickiness		
Homogeneous capital ($\xi_{p,hom}$)	0.8392	0.6995	0.7890	0.4628	0.8958
	(-)	(-)	(-)	(-)	(-)
Firm-specific capital ($\xi_{p,fs}$)	0.3862	0.1232	0.5326	0.1458	0.8884
	(-)	(-)	(-)	(-)	(-)

Phillips Curve Slope in VAR 10 is a monster, is 0.6 omplitely messed up.

Table 5: (VAR Aligned) Implied Average Time between Re-Optimization

Model Spec.	**VAR** $p = 4$	**VAR** $p = 6$	**VAR** $p = 8$	**VAR** $p = 10$	**VAR** $p = 12$
Homogeneous Capital Model					
Calvo ($\xi_{p,hom}$)	0.84	0.70	0.79	0.46	0.90
Duration (quarters)	**6.2**	**3.3**	**4.7**	**1.9**	**9.6**
Firm-Specific Capital Model					
Calvo ($\xi_{p,fs}$)	0.39	0.12	0.53	0.15	0.89
Duration (quarters)	**1.6**	**1.1**	**2.1**	**1.2**	**9.0**

- **Baseline VAR** ($p = 4$): Homogeneous capital implies price changes every **6.2 quarters**.
- **Firm-specific capital**: Drastically reduces this to **1.6 quarters**, matching microeconomic evidence.

Note: Implied duration is calculated as $D = 1/(1 - \xi_p)$.

Results are robust to this exercise, no major changes, but this exercise exacerbates the Phillips Curve Slope of the DSGE when estimated matching with the VAR 6 and expecially 10. When using the VAR 10 the DSGE Phillips curve is tremendously hig 0.6 –¿ this is the driver of the low implied time from the calvo parameter, hence the ACEL result seems to to be robust by increasing the lag choice, an expecially there are some problems with the Phillips curve when chooising 6 and 10 lags
